D200, Problem Set 3: Reinforcement Learning

Due: 5 March 2026 here in groups of up to 2.

Stefan Bucher

This problem set introduces reinforcement learning through three economic applications from IO and quantitative marketing. You will progress from multi-armed bandits (ad-channel testing) to tabular Q-learning (airline revenue management) to Deep Q-Networks (within-session content personalisation). Each problem is self-contained: the key RL concepts are explained before you need them.

Problem 1: Multi-Armed Bandits for Ad Channel Selection

The exploration-exploitation dilemma. Suppose a firm can advertise through several marketing channels but doesn't know which channel converts customers most effectively. If the firm always uses the channel that *looks* best so far (exploitation), it might miss a better option it hasn't tried enough. If it keeps experimenting with all channels equally (exploration), it wastes budget on poor performers. *Multi-armed bandits* formalise this tradeoff: an agent repeatedly chooses one of K "arms" (here, ad channels), observes a reward (conversion or not), and must learn which arm is best while minimising total reward lost from suboptimal choices. This is the simplest reinforcement learning setting — there is no state, no dynamics, just a repeated decision under uncertainty.

Environment

The `AdChannelBandit` below simulates $K = 5$ marketing channels. Each time you select a channel, a customer either converts (reward = 1) or does not (reward = 0), drawn from a Bernoulli distribution with an unknown channel-specific conversion rate. The firm's goal is to maximise total conversions over T rounds.

```
class AdChannelBandit:
    """K-armed bandit for ad channel selection with Bernoulli rewards."""

    def __init__(self):
```

```python
        self.channels = ["Email", "Social Media", "Display Ads", "Search", "Influencer"]
        self.K = len(self.channels)
        self._rates = np.array([0.08, 0.15, 0.12, 0.25, 0.05])

    def pull(self, arm):
        """Select a channel and observe conversion (1) or not (0)."""
        return np.random.binomial(1, self._rates[arm])

    def optimal_arm(self):
        """Index of the channel with the highest true conversion rate."""
        return np.argmax(self._rates)

    def expected_reward(self, arm):
        """True conversion rate of the given channel (used for regret calculation)."""
        return self._rates[arm]

bandit = AdChannelBandit()
print("Channels:", bandit.channels)
print(f"Number of arms (K): {bandit.K}")
```

```
Channels: ['Email', 'Social Media', 'Display Ads', 'Search', 'Influencer']
Number of arms (K): 5
```

(1a) As a baseline, run a **random policy** that selects a channel uniformly at random each round for $T = 2000$ rounds. Plot:

1. **Cumulative reward** (total conversions over time)
2. **Cumulative regret** over time

Regret measures the cost of not always pulling the best arm. Define per-round regret as $p^* - p_{a_t}$, where $p^* = \max_k p_k$ is the best channel's true conversion rate and p_{a_t} is the conversion rate of the channel chosen at round t. Cumulative regret sums this over all rounds:

$$R_T = \sum_{t=1}^{T} \left(p^* - p_{a_t}\right)$$

Hint: a random policy has constant expected per-round regret, so cumulative regret grows linearly.

```python
def run_random(bandit, T=2000):
    """Run a random policy for T rounds.

    Returns:
        rewards: array of length T, reward at each round (0 or 1)
        arms_played: array of length T, index of arm chosen each round
    """
    # TODO: implement
    pass

# Run the random policy and plot cumulative reward and cumulative regret
```

Solution:

```python
np.random.seed(42)

def run_random(bandit, T=2000):
    rewards = np.zeros(T)
    arms_played = np.zeros(T, dtype=int)
    for t in range(T):
        arm = np.random.randint(bandit.K)
        rewards[t] = bandit.pull(arm)
        arms_played[t] = arm
    return rewards, arms_played

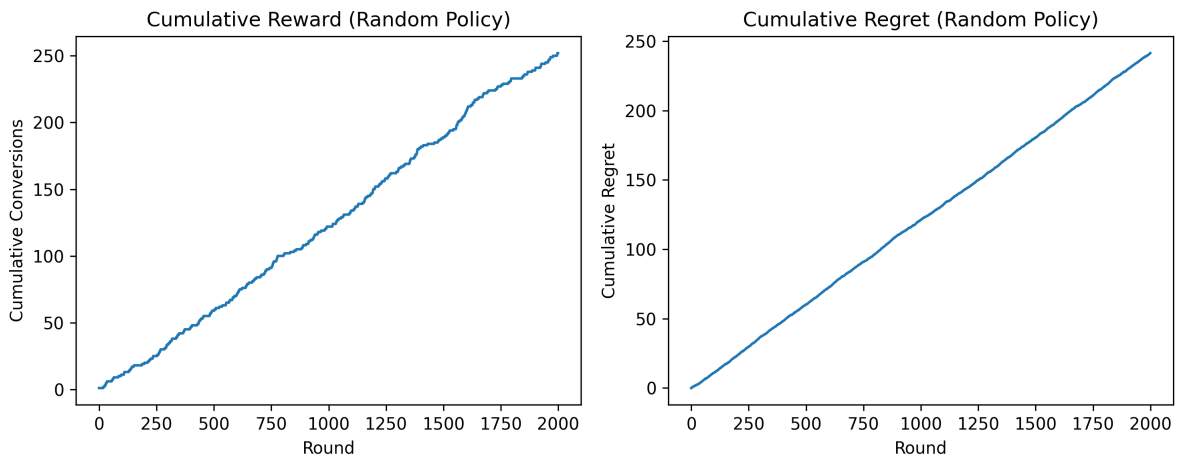
rewards_rand, arms_rand = run_random(bandit, T=2000)
p_star = bandit.expected_reward(bandit.optimal_arm())

fig, axes = plt.subplots(1, 2, figsize=(10, 4))

axes[0].plot(np.cumsum(rewards_rand))
axes[0].set_xlabel("Round")
axes[0].set_ylabel("Cumulative Conversions")
axes[0].set_title("Cumulative Reward (Random Policy)")

per_round_regret = p_star - np.array([bandit.expected_reward(a) for a in arms_rand])
axes[1].plot(np.cumsum(per_round_regret))
axes[1].set_xlabel("Round")
axes[1].set_ylabel("Cumulative Regret")
axes[1].set_title("Cumulative Regret (Random Policy)")
```

```
plt.tight_layout()
plt.show()
```



(1b) Implement the following three bandit algorithms and compare them (plus the random baseline) on a single cumulative regret plot over $T = 2000$ rounds, averaged over 50 independent runs.

1. **ϵ-greedy ($\epsilon = 0.1$):** With probability ϵ, choose a random arm; otherwise choose the arm with the highest empirical mean reward. Update means incrementally: $\bar{r}_a \leftarrow \bar{r}_a + \frac{1}{n_a}(r_t - \bar{r}_a)$.
2. **UCB1 ($c = 2$):** Pull each arm once, then choose $\arg\max_a \left[\bar{r}_a + c\sqrt{\frac{\ln t}{n_a}}\right]$ where n_a is the number of times arm a has been pulled.
3. **Thompson Sampling:** Maintain a $\text{Beta}(\alpha_a, \beta_a)$ posterior for each arm (initialised at $\text{Beta}(1, 1)$, the uniform prior). Each round, sample $\theta_a \sim \text{Beta}(\alpha_a, \beta_a)$ for every arm and pull $\arg\max_a \theta_a$. On observing reward $r_t \in \{0, 1\}$, update: $\alpha_a \leftarrow \alpha_a + r_t$, $\beta_a \leftarrow \beta_a + (1 - r_t)$.

Each function should return `(rewards, arms_played)` arrays of length T, just like `run_random`.

```
def epsilon_greedy(bandit, T=2000, epsilon=0.1):
    """Epsilon-greedy algorithm."""
    # TODO: implement
    pass

def ucb1(bandit, T=2000, c=2.0):
    """UCB1 algorithm."""
    # TODO: implement
```

```
    pass

def thompson_sampling(bandit, T=2000):
    """Thompson Sampling with Beta(1,1) priors."""
    # TODO: implement
    pass

# Run each algorithm for 50 independent runs and plot average cumulative regret
```

Solution:

```
np.random.seed(42)

def epsilon_greedy(bandit, T=2000, epsilon=0.1):
    K = bandit.K
    counts = np.zeros(K)
    values = np.zeros(K)
    rewards = np.zeros(T)
    arms_played = np.zeros(T, dtype=int)

    for t in range(T):
        if np.random.random() < epsilon:
            arm = np.random.randint(K)
        else:
            arm = np.argmax(values)

        reward = bandit.pull(arm)
        counts[arm] += 1
        values[arm] += (reward - values[arm]) / counts[arm]
        rewards[t] = reward
        arms_played[t] = arm

    return rewards, arms_played

def ucb1(bandit, T=2000, c=2.0):
    K = bandit.K
    counts = np.zeros(K)
    values = np.zeros(K)
    rewards = np.zeros(T)
    arms_played = np.zeros(T, dtype=int)

    for arm in range(K):
```

```
        reward = bandit.pull(arm)
        counts[arm] = 1
        values[arm] = reward
        rewards[arm] = reward
        arms_played[arm] = arm

    for t in range(K, T):
        ucb_values = values + c * np.sqrt(np.log(t) / counts)
        arm = np.argmax(ucb_values)

        reward = bandit.pull(arm)
        counts[arm] += 1
        values[arm] += (reward - values[arm]) / counts[arm]
        rewards[t] = reward
        arms_played[t] = arm

    return rewards, arms_played

```

(1c) Answer the following in 2–3 sentences each (no code needed):

1. Which of the three algorithms learns fastest (achieves lowest cumulative regret)? Why does it outperform the others?

2. A marketing manager proposes: *"Let's just test each of the 5 channels equally for 400 rounds each, then pick the winner."* What is the cumulative regret of this uniform-testing strategy over the full $T = 2000$ rounds, and why do adaptive algorithms do better?

Solution:

1. **Thompson Sampling** typically achieves the lowest cumulative regret. It outperforms the others because it directs exploration toward arms that are *plausibly optimal* — uncertain arms that might be the best — rather than exploring uniformly at random (ϵ-greedy) or using a deterministic upper bound that can over-explore (UCB1). As the posterior concentrates around the true rates, Thompson Sampling naturally shifts almost entirely to exploitation.

2. Under uniform testing, each of the four suboptimal arms is pulled 400 times. The cumulative regret is $\sum_{k \neq k^*} 400 \cdot (p^* - p_k) = 400(0.17 + 0.10 + 0.13 + 0.20) = 240$. This is the same regret as the purely random policy, because both allocate equal trials to each arm over the full horizon. Adaptive algorithms achieve far less regret (typically < 50) because they learn within the first few hundred rounds to concentrate pulls on the best arm, rather than wasting budget on channels that are clearly inferior.

Problem 2: Airline Revenue Management via Reinforcement Learning

In Problem 1 the firm chose prices without state — each round was independent. Real pricing problems are richer: an airline has a *finite* number of seats and a *finite* selling horizon, so today's optimal fare depends on how many seats remain and how many days are left before departure. This kind of sequential decision-making under uncertainty is formalised as a **Markov Decision Process (MDP)**, defined by states $\mathcal{S}$ (what the agent observes), actions $\mathcal{A}$ (what it can do), a reward function $R(s, a)$ (immediate payoff), transition probabilities $P(s' \mid s, a)$ (how the world evolves), and a discount factor $\gamma \in [0, 1]$ (how much the agent values future versus present rewards).

The key recursive insight is the **Bellman equation**: $V(s) = \max_a \big[\mathbb{E}[r \mid s, a] + \gamma\, \mathbb{E}[V(s') \mid s, a]\big]$. When the model ($P$ and R) is known, **value iteration** applies this equation to every state until convergence, yielding the optimal policy $\pi^*(s) = \arg\max_a [\cdots]$. When the model is *unknown*, **Q-learning** learns action-values directly from data using the update $Q(s, a) \leftarrow Q(s, a) + \alpha\big[r + \gamma \max_{a'} Q(s', a') - Q(s, a)\big]$ — the agent simply interacts with the environment and refines its estimates, requiring no knowledge of P or R.

Environment

The `AirlinePricingEnv` below models an airline selling $N = 10$ seats on a flight departing in $T = 25$ days (a small state space so that tabular Q-learning can learn a policy close to the optimal one). Each day the airline chooses one of five fare classes. One potential passenger arrives and buys (or not) according to a logit demand model — the same functional form as PS2's discrete choice, with $P(\text{buy}) = \frac{1}{1+\exp(-(\alpha+\beta\cdot\text{price}))}$.

```
import gymnasium
from gymnasium import spaces

class AirlinePricingEnv(gymnasium.Env):
    """Airline revenue management environment.

    State: (seats_remaining, days_to_departure)
    Action: one of 5 fare classes
    Reward: fare if passenger buys, 0 otherwise
    Terminal: departure day reached or sold out

    Default: 10 seats, 25 days (small state space so Q-learning can match VI well).
    """

    def __init__(self, max_seats=10, max_days=25, alpha=5.0, beta=-0.02):
        super().__init__()
        self.max_seats = max_seats
        self.max_days = max_days
        self.alpha = alpha
        self.beta = beta
        self.fares = np.array([100, 200, 300, 400, 500])

        self.observation_space = spaces.MultiDiscrete([max_seats + 1, max_days + 1])
        self.action_space = spaces.Discrete(len(self.fares))

    def demand_prob(self, price):
        """P(buy) = 1 / (1 + exp(-(alpha + beta * price)))"""
        return 1.0 / (1.0 + np.exp(-(self.alpha + self.beta * price)))

    def reset(self, seed=None, options=None):
        super().reset(seed=seed)
        self.seats_remaining = self.max_seats
        self.days_to_departure = self.max_days
        return self._get_obs(), {}
```

```python
    def _get_obs(self):
        return np.array([self.seats_remaining, self.days_to_departure])

    def step(self, action):
        price = self.fares[action]

        if self.seats_remaining > 0:
            p = self.demand_prob(price)
            bought = int(self.np_random.binomial(1, p))
            reward = float(price * bought)
            self.seats_remaining -= bought
        else:
            reward = 0.0

        self.days_to_departure -= 1
        terminated = (self.days_to_departure == 0) or (self.seats_remaining == 0)
        truncated = False

        return self._get_obs(), reward, terminated, truncated, {}

env = AirlinePricingEnv()

price_grid = np.linspace(50, 600, 200)
fig, axes = plt.subplots(1, 2, figsize=(10, 3.5))
axes[0].plot(price_grid, env.demand_prob(price_grid))
axes[0].scatter(env.fares, env.demand_prob(env.fares), c='red', zorder=5)
axes[0].set_xlabel('Fare (£)')
axes[0].set_ylabel('P(buy)')
axes[0].set_title('Logit Demand Curve')

axes[1].plot(price_grid, price_grid * env.demand_prob(price_grid))

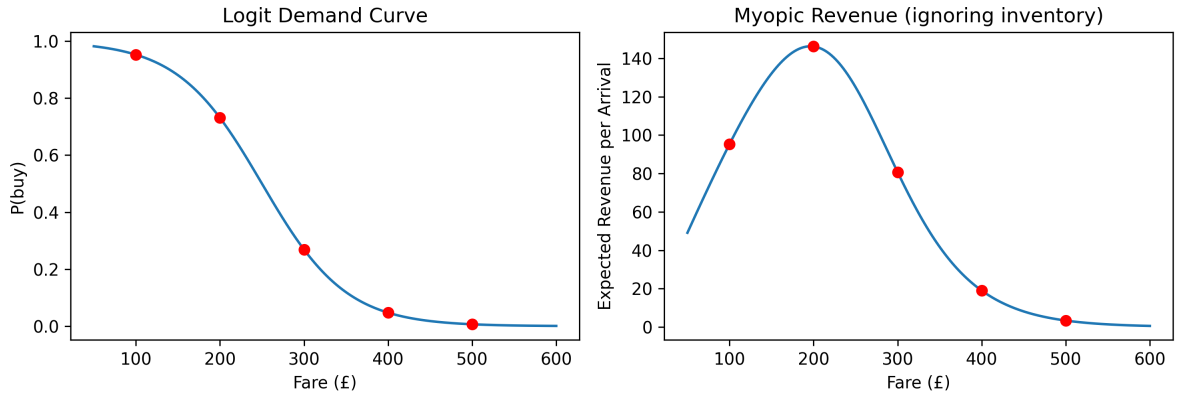
plt.tight_layout()
plt.show()

print(f"Observation space: {env.observation_space}")
print(f"Action space:      {env.action_space}  (fares = {env.fares})")
print(f"Purchase probs:    {dict(zip(env.fares, np.round(env.demand_prob(env.fares), 3)))}")
```



```
Observation space: MultiDiscrete([11 26])
Action space:      Discrete(5)  (fares = [100 200 300 400 500])
Purchase probs:    {100: 0.953, 200: 0.731, 300: 0.269, 400: 0.047, 500: 0.007}
```

(2a) MDP formulation. Write down the components of this MDP:

1. State space $\mathcal{S}$: what variables define a state? How large is $|\mathcal{S}|$?
2. Action space $\mathcal{A}$: what does the agent choose?
3. Reward $R(s, a)$: what is the expected immediate reward?
4. Transition $P(s' \mid s, a)$: given the Bernoulli demand, what are the possible next states and their probabilities?
5. What economic interpretation does the discount factor γ have here?
6. When does an episode terminate?

Solution:

1. **State space:** $\mathcal{S} = \{0, \dots, 10\} \times \{0, \dots, 25\}$ — all pairs (seats_remaining, days_to_departure). Size: $11 \times 26 = 286$.
2. **Action space:** $\mathcal{A} = \{0, 1, 2, 3, 4\}$ corresponding to fares $\{100, 200, 300, 400, 500\}$.
3. **Reward:** $\mathbb{E}[R \mid s, a] = \text{fare}_a \cdot p_a$ where $p_a = \sigma(\alpha + \beta \cdot \text{fare}_a)$. The reward depends on the action but not on the state (except that the episode is terminal when $n = 0$).
4. **Transition:** From state (n, d) with $n \geq 1$, choosing action a:
   - With probability p_a: next state is $(n{-}1,\ d{-}1)$ (passenger buys).
   - With probability $1 - p_a$: next state is $(n,\ d{-}1)$ (no purchase).
5. **Discount factor:** γ captures the time value of money — revenue today is worth more than revenue tomorrow. With $\gamma = 0.99$ over 50 periods, $\gamma^{50} \approx 0.61$.
6. **Terminal conditions:** $d = 0$ (departure) or $n = 0$ (sold out).

(2b) Value iteration (known demand). Suppose the airline knows the demand function (i.e. it knows α and β). Implement value iteration to compute the optimal value function and policy. For non-terminal states (s, d) with $s \geq 1$, $d \geq 1$:

$$V(s, d) = \max_a \left[p_a(\text{fare}_a + \gamma V(s{-}1,\, d{-}1)) + (1 - p_a)\, \gamma V(s,\, d{-}1) \right]$$

where $p_a = P(\text{buy} \mid \text{fare}_a)$. Sweep over all states until $\max_{s,d} |V^{\text{new}} - V^{\text{old}}| < \texttt{tol}$. Then plot the optimal fare as a heatmap over (seats_remaining, days_to_departure).

```
def value_iteration(env, gamma=0.99, tol=1e-6):
    """Compute optimal V and policy by value iteration.

    Returns:
        V: np.array shape (max_seats+1, max_days+1)
        policy: np.array shape (max_seats+1, max_days+1), optimal action index
    """
    pass
```

Solution:

```
def value_iteration(env, gamma=0.99, tol=1e-6):
    S, D = env.max_seats + 1, env.max_days + 1
    n_actions = len(env.fares)
    probs = env.demand_prob(env.fares)

    V = np.zeros((S, D))

    while True:
        delta = 0.0
        for s in range(1, S):
            for d in range(1, D):
                v_old = V[s, d]
                best = -np.inf
                for a in range(n_actions):
                    p = probs[a]
                    val = p * (env.fares[a] + gamma * V[s - 1, d - 1]) \
                        + (1 - p) * gamma * V[s, d - 1]
                    if val > best:
                        best = val
                V[s, d] = best
                delta = max(delta, abs(V[s, d] - v_old))
```

```
        if delta < tol:
            break

    policy = np.zeros((S, D), dtype=int)
    for s in range(1, S):
        for d in range(1, D):
            best_a, best_val = 0, -np.inf
            for a in range(n_actions):
                p = probs[a]
                val = p * (env.fares[a] + gamma * V[s - 1, d - 1]) \
                    + (1 - p) * gamma * V[s, d - 1]
                if val > best_val:
                    best_val = val
                    best_a = a
            policy[s, d] = best_a

    return V, policy

V_star, pi_star = value_iteration(env)

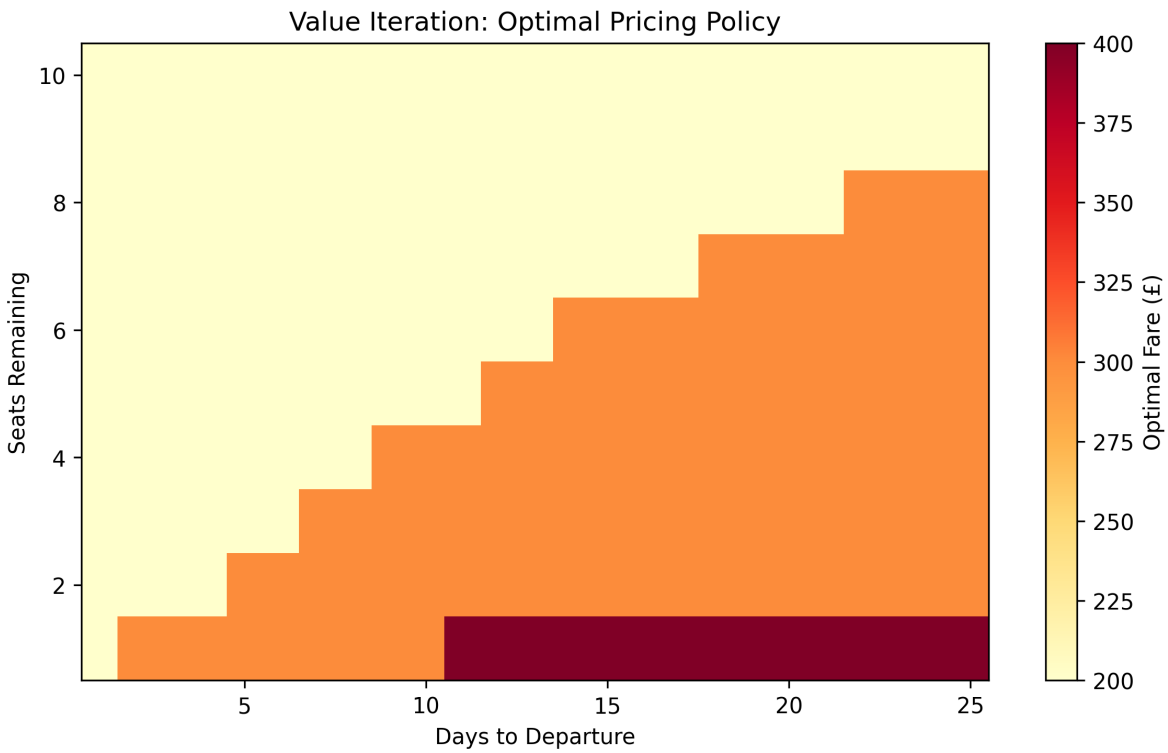
                extent=[0.5, env.max_days + 0.5, 0.5, env.max_seats + 0.5],
                cmap='YlOrRd')
plt.colorbar(im, label='Optimal Fare (£)')
plt.xlabel('Days to Departure')
plt.ylabel('Seats Remaining')
plt.title('Value Iteration: Optimal Pricing Policy')
plt.tight_layout()
plt.show()

print(f"Value of starting state V({env.max_seats}, {env.max_days}) = £{V_star[env.max_seats,
```



```
Value of starting state V(10, 25) = £2149
```

(2c) Q-learning (unknown demand). Now suppose the airline does *not* know the demand function. Implement tabular Q-learning with ϵ-greedy exploration. Train for **10,000 episodes** and use **decaying exploration**: e.g. $\epsilon = \max(0.01, 0.4 - \text{episode}/12000)$ so that the agent explores less as it learns. Plot the learning curve (episode reward smoothed over 100 episodes).

$$Q(s,a) \leftarrow Q(s,a) + \alpha\big[r + \gamma \max_{a'} Q(s',a') - Q(s,a)\big]$$

```python
def q_learning(env, n_episodes=10000, alpha=0.1, gamma=0.99, epsilon_start=0.4, epsilon_end=0
    """Tabular Q-learning with epsilon-greedy exploration.

    Returns:
        Q: dict mapping (seats, days, action) -> value
        episode_rewards: list of total reward per episode
    """
    pass
```

Solution:

```
def q_learning(env, n_episodes=10000, alpha=0.1, gamma=0.99, epsilon_start=0.4, epsilon_end=0
    Q = {}
    episode_rewards = []

    def get_q(s, d, a):
        return Q.get((s, d, a), 0.0)

    for ep in range(n_episodes):
        epsilon = max(epsilon_end, epsilon_start - ep / 12000)
        obs, _ = env.reset()
        seats, days = int(obs[0]), int(obs[1])
        total_reward = 0.0
        terminated = False

        while not terminated:
            if np.random.random() < epsilon:
                action = env.action_space.sample()
            else:
                q_vals = [get_q(seats, days, a) for a in range(env.action_space.n)]
                action = int(np.argmax(q_vals))

            next_obs, reward, terminated, truncated, _ = env.step(action)
            next_seats, next_days = int(next_obs[0]), int(next_obs[1])
            total_reward += reward

```

```
Mean reward (last 500 episodes): £2062
```

(2d) Compare policies. Extract the greedy policy from Q (for each state, the action with highest Q-value) and plot it as a heatmap side-by-side with the value-iteration policy from (2b). How closely does Q-learning recover the optimal policy? When would you prefer each approach? (If the two heatmaps look very different, try training Q-learning for more episodes or using a decaying ϵ so that exploration decreases over time.)

Solution:

```python
q_policy = np.zeros((env.max_seats + 1, env.max_days + 1), dtype=int)
for s in range(1, env.max_seats + 1):
    for d in range(1, env.max_days + 1):
        q_vals = [Q_table.get((s, d, a), 0.0) for a in range(env.action_space.n)]
        q_policy[s, d] = np.argmax(q_vals)

q_fare_map = np.array(env.fares)[q_policy]
vi_fare_map = np.array(env.fares)[pi_star]

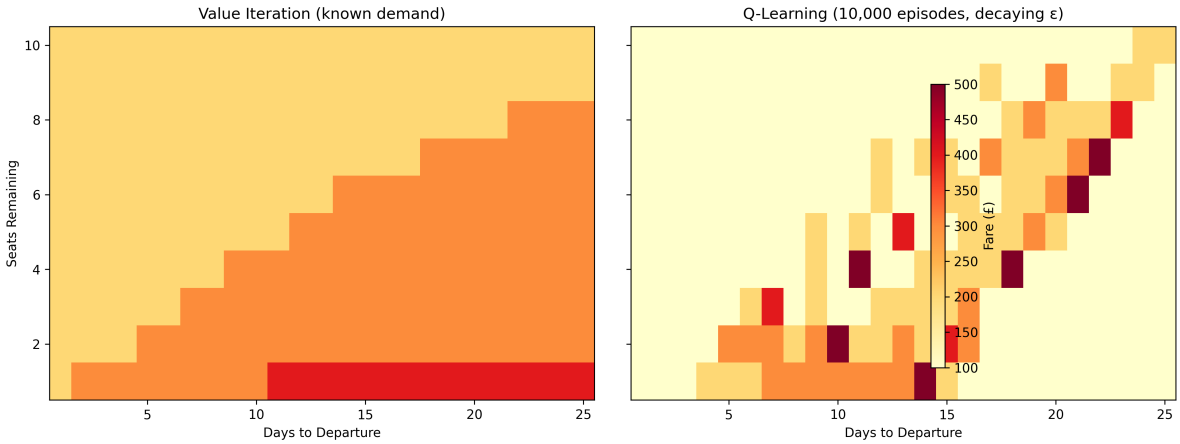
fig, axes = plt.subplots(1, 2, figsize=(13, 5), sharey=True)

im0 = axes[0].imshow(vi_fare_map[1:, 1:], origin='lower', aspect='auto',
                     extent=[0.5, env.max_days + 0.5, 0.5, env.max_seats + 0.5],
                     cmap='YlOrRd', vmin=100, vmax=500)
axes[0].set_xlabel('Days to Departure')
axes[0].set_ylabel('Seats Remaining')
axes[0].set_title('Value Iteration (known demand)')

im1 = axes[1].imshow(q_fare_map[1:, 1:], origin='lower', aspect='auto',
                     extent=[0.5, env.max_days + 0.5, 0.5, env.max_seats + 0.5],
                     cmap='YlOrRd', vmin=100, vmax=500)
axes[1].set_xlabel('Days to Departure')
axes[1].set_title('Q-Learning (10,000 episodes, decaying )')

fig.colorbar(im1, ax=axes, label='Fare (£)', shrink=0.8)
plt.tight_layout()
plt.show()

agreement = np.mean(pi_star[1:, 1:] == q_policy[1:, 1:])
print(f"Policy agreement: {agreement:.1%} of states match")
```



```
Policy agreement: 11.6% of states match
```

Discussion. Both policies share the same broad structure: charge higher fares when seats are scarce relative to remaining time, and lower fares when inventory is plentiful. Q-learning's policy is noisier — particularly in rarely-visited states — because it must *discover* the demand function through trial and error, while value iteration exploits exact knowledge of $P(\text{buy} \mid \text{fare})$.

This parallels a classic distinction in structural econometrics. Rust (1987) solved Harold Zurcher's bus-engine replacement problem by assuming the agent knows the transition model and solving the Bellman equation — exactly what value iteration does in (2b). Q-learning takes the model-free approach: no assumptions about demand, learning purely from observed outcomes. The structural (model-based) approach gives the exact optimum when the model is correctly specified; Q-learning is more robust when the demand model is misspecified or unknown, at the cost of requiring more data and producing noisier policies.

Problem 3: Deep Q-Networks for Content Personalisation

In Problem 2, tabular Q-learning worked because every (inventory, time) state could be visited many times. But most real applications have states that are high-dimensional or continuous — think of a user's full browsing history or click pattern across dozens of content categories. We cannot store a separate Q-value for every possible state.

Deep Q-Networks (DQN) solve this by replacing the Q-table with a neural network $Q_\theta(s, a)$ that takes a state vector as input and outputs Q-values for all actions. Because the network *generalises* across similar states, it can estimate Q-values for states never seen during training. Two techniques stabilise learning: a **replay buffer** (stores past transitions and samples random mini-batches to break temporal correlation) and a **target network** (a slowly-updated copy

of Q_θ used to compute Bellman targets, preventing the "moving target" problem). We apply DQN to within-session content personalisation: a platform must learn each visitor's preferences during a single browsing session by observing their clicks, then serve content that maximises conversion.

Environment

```
import gymnasium
from gymnasium import spaces
from itertools import combinations
from scipy.special import expit

class ContentPersonalizationEnv(gymnasium.Env):
    """
    Within-session content personalisation.

    A platform displays K=3 of M=5 content categories at each page view.
    The visitor (one of 3 latent types) clicks according to an MNL model
    over the displayed categories plus an outside option.  At session end,
    conversion probability depends on how well displayed content matched
    the visitor's true preferences.
    """

(3a) Understanding DQN and running training. The code below implements a DQN agent: a **replay buffer** (stores past transitions and samples random mini-batches to break correlation), a **target network** (a copy of the Q-network updated every 10 episodes so that Bellman targets do not change too quickly), and a **training loop** with ϵ-greedy exploration (decaying from 1.0 to 0.01 over 300 episodes).

Your task:

1. **Implement the `QNetwork`** in PyTorch: input dimension 7 (state), two hidden layers of 128 units with ReLU, output dimension 10 (one Q-value per action). This is the only part you need to write.
2. **Run the provided training loop** (it uses your `QNetwork` and the provided `ReplayBuffer`). Plot the learning curve (conversion rate over episodes).
3. **Short answer:** Why do we use a replay buffer instead of updating on every single transition? Why do we use a separate target network instead of using the same network for both the current Q and the Bellman target?

```python
import torch
import torch.nn as nn
import torch.optim as optim
from collections import deque
import random

class QNetwork(nn.Module):
    """Q-network: state (7-dim) -> hidden -> hidden -> Q-values (10 actions)."""
    def __init__(self, state_dim=7, n_actions=10):
        super().__init__()
        # TODO: define self.net as Sequential: Linear(7,128), ReLU, Linear(128,128), ReLU, Li
        pass

    def forward(self, x):
        return self.net(x)

class ReplayBuffer:
    """Stores (s, a, r, s', done) and samples random batches. Provided for you."""
    def __init__(self, capacity=10000):
        self.buffer = deque(maxlen=capacity)
```

```
    def push(self, state, action, reward, next_state, done):
        self.buffer.append((state, action, reward, next_state, done))

    def sample(self, batch_size):
        batch = random.sample(self.buffer, batch_size)
        states, actions, rewards, next_states, dones = zip(*batch)
        return (
            torch.FloatTensor(np.array(states)),
            torch.LongTensor(actions),
            torch.FloatTensor(rewards),
            torch.FloatTensor(np.array(next_states)),
            torch.FloatTensor(dones),
        )

    def __len__(self):
        return len(self.buffer)

# Run the training loop below after you have defined QNetwork above.
```

The training loop is provided in the solution so you can see the full DQN algorithm (epsilon-greedy, Bellman update, target network sync). Once your `QNetwork` is defined, the solution runs this loop and plots the learning curve.

Solution:

1. QNetwork:

```
import torch
import torch.nn as nn
import torch.optim as optim
from collections import deque
import random

torch.manual_seed(42)

class QNetwork(nn.Module):
    def __init__(self, state_dim=7, n_actions=10):
        super().__init__()
        self.net = nn.Sequential(
            nn.Linear(state_dim, 128),
            nn.ReLU(),
```

```
            nn.Linear(128, 128),
            nn.ReLU(),
            nn.Linear(128, n_actions),
        )

    def forward(self, x):
        return self.net(x)

class ReplayBuffer:
    def __init__(self, capacity=10000):
        self.buffer = deque(maxlen=capacity)
    def push(self, state, action, reward, next_state, done):
        self.buffer.append((state, action, reward, next_state, done))
    def sample(self, batch_size):
        batch = random.sample(self.buffer, batch_size)
        states, actions, rewards, next_states, dones = zip(*batch)
        return (
            torch.FloatTensor(np.array(states)),
            torch.LongTensor(actions),
            torch.FloatTensor(rewards),
            torch.FloatTensor(np.array(next_states)),
            torch.FloatTensor(dones),
        )
    def __len__(self):
        return len(self.buffer)
```

2. Training (full loop for reference):

```
env = ContentPersonalizationEnv()
q_net = QNetwork()
target_net = QNetwork()
target_net.load_state_dict(q_net.state_dict())

optimizer = optim.Adam(q_net.parameters(), lr=1e-3)
replay_buffer = ReplayBuffer(capacity=10000)

n_episodes = 500
gamma = 0.99
batch_size = 32
conversions = []

for episode in range(n_episodes):
```

```
    epsilon = max(0.01, 1.0 - episode / 300)
    obs, info = env.reset()
    done = False

    while not done:
        if random.random() < epsilon:
            action = env.action_space.sample()
        else:
            with torch.no_grad():
                q_vals = q_net(torch.FloatTensor(obs).unsqueeze(0))
                action = q_vals.argmax(1).item()

        next_obs, reward, terminated, truncated, info = env.step(action)
        done = terminated or truncated
        replay_buffer.push(obs, action, reward, next_obs, float(done))
        obs = next_obs

        if len(replay_buffer) >= batch_size:
            s_b, a_b, r_b, ns_b, d_b = replay_buffer.sample(batch_size)
            current_q = q_net(s_b).gather(1, a_b.unsqueeze(1))
            with torch.no_grad():
                next_q = target_net(ns_b).max(1)[0]
                target_q = r_b + gamma * next_q * (1 - d_b)
            loss = nn.MSELoss()(current_q.squeeze(), target_q)
            optimizer.zero_grad()
            loss.backward()
            optimizer.step()

    conversions.append(reward)

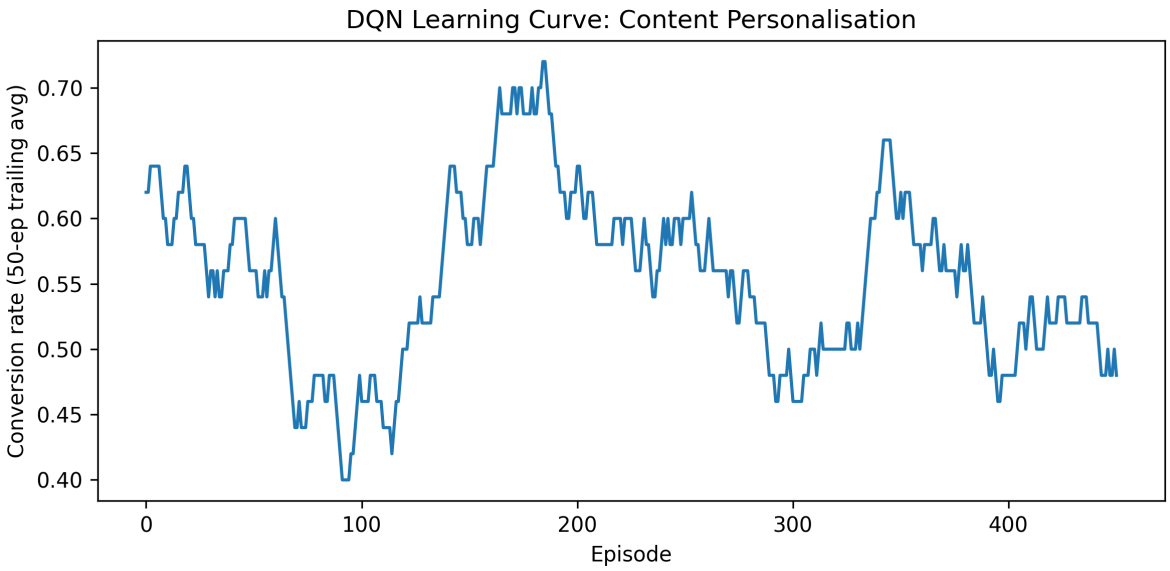
    if episode % 10 == 0:
        target_net.load_state_dict(q_net.state_dict())

# --- Plot learning curve ---
window = 50
smoothed = np.convolve(conversions, np.ones(window) / window, mode="valid")

plt.figure(figsize=(8, 4))
plt.plot(smoothed)
plt.xlabel("Episode")
plt.ylabel(f"Conversion rate ({window}-ep trailing avg)")
plt.title("DQN Learning Curve: Content Personalisation")
```

```
plt.tight_layout()
plt.show()

print(f"Final conversion rate (last 100 episodes): {np.mean(conversions[-100:]):.3f}")
```



```
Final conversion rate (last 100 episodes): 0.480
```

3. Short answer — why replay buffer and target network?

- **Replay buffer:** Consecutive transitions (s_t, a_t, r_t, s_{t+1}) are strongly correlated (e.g. similar states). If we update the network only on the current transition, the gradient is biased by this correlation and learning can be unstable. Sampling *random* mini-batches from a buffer breaks this correlation and gives more i.i.d.-like updates, which stabilises training.
- **Target network:** The Bellman target $r + \gamma \max_{a'} Q(s', a')$ depends on the same Q we are updating. So the target moves with every step, making the learning target a "moving goalpost." Using a separate network that is updated only every 10 episodes keeps the target fixed over many updates, so the agent can converge toward a stable target.

(3b) Comparison with stable-baselines3. The plot below compares our DQN's learning curve (from 3a) with one produced by the `stable-baselines3` library (same environment, similar hyperparameters). You do not need to run SB3 yourself.

Describe what the library implementation does differently from our minimal DQN (e.g. loss function, gradient handling, exploration schedule). Why might its curve look different from ours?

Solution:

Stable-baselines3's DQN includes several refinements that our minimal implementation in (3a) does not:

- **Huber loss** instead of MSE for the Bellman error, which is less sensitive to large target outliers and can make learning more stable.
- **Gradient clipping** (by norm) to prevent occasional large gradients from destabilising updates.
- **Exploration schedule** defined over *timesteps* rather than episodes, with configurable linear decay.
- **Double DQN** (optional): uses the current network to select the best next action and the target network to evaluate it, reducing overestimation of Q-values.
- **Efficient replay sampling** and vectorised environments for faster training.

Because of these differences, the SB3 learning curve may converge faster or to a slightly higher conversion rate, or look smoother. The main takeaway is that production RL libraries add many small stabilisation tricks on top of the core DQN idea (replay + target network).

Optional: If you have `stable-baselines3` installed, you can generate a direct comparison by training SB3's DQN on `ContentPersonalizationEnv` for the same number of timesteps and plotting both curves. The code is in the repository for reference.

(3c) Interpret the learned policy:

1. For each visitor type, record which assortments the trained DQN selects during the **early** phase (steps 1–3) versus the **late** phase (steps 6–8). Does the agent explore early and exploit late?
2. Compare the DQN's conversion rate against a **static policy** that always displays the 3 globally most popular categories. How much does personalisation improve conversion?

Solution:

```
from collections import Counter

n_eval = 200
type_early = {t: [] for t in range(3)}
type_late = {t: [] for t in range(3)}
dqn_conv = {t: [] for t in range(3)}

for _ in range(n_eval):
    obs, info = env.reset()
    vtype = info["visitor_type"]
    step = 0
    done = False
```

```
    while not done:
        with torch.no_grad():
            action = q_net(torch.FloatTensor(obs).unsqueeze(0)).argmax(1).item()
        step += 1
        if step <= 3:
            type_early[vtype].append(action)
        if step >= 6:
            type_late[vtype].append(action)
        obs, reward, terminated, truncated, info = env.step(action)
        done = terminated or truncated
    dqn_conv[vtype].append(reward)

# --- Static baseline: always show the top-3 globally popular categories ---
avg_utility = env.TYPE_UTILITIES.mean(axis=0)
top3_global = tuple(sorted(np.argsort(avg_utility)[-3:]))
static_action = env.assortments.index(top3_global)
static_cats = [env.CATEGORIES[j] for j in top3_global]
print(f"Static policy: always show {static_cats} (action {static_action})\n")

static_conv = {t: [] for t in range(3)}
for _ in range(n_eval):
    obs, info = env.reset()
    vtype = info["visitor_type"]
    done = False
    while not done:
        obs, reward, terminated, truncated, info = env.step(static_action)
        done = terminated or truncated
    static_conv[vtype].append(reward)

# --- Conversion comparison ---

            for a, c in counts
        )
        print(f"    {label}: {desc}")
```

```
Static policy: always show ['Tech', 'Fashion', 'Sports'] (action 0)

Conversion rates by visitor type:
Type                      DQN   Static     Lift
-----------------------------------------------
Tech enthusiast         0.516    0.487    +6.0%
Fashionista             0.492    0.646   -23.8%
Sports fan              0.589    0.695   -15.2%
Overall                 0.535    0.600   -10.8%

Most frequent assortments by phase:

  Tech enthusiast:
    Steps 1-3: ['Tech', 'Sports', 'Food'] (55%); ['Tech', 'Food', 'Travel'] (31%); ['Fashion
    Steps 6-8: ['Tech', 'Sports', 'Food'] (25%); ['Tech', 'Fashion', 'Food'] (23%); ['Tech',

  Fashionista:
    Steps 1-3: ['Tech', 'Sports', 'Food'] (51%); ['Tech', 'Food', 'Travel'] (34%); ['Fashion
    Steps 6-8: ['Tech', 'Fashion', 'Travel'] (22%); ['Fashion', 'Sports', 'Food'] (16%); ['Te

  Sports fan:
    Steps 1-3: ['Tech', 'Sports', 'Food'] (42%); ['Fashion', 'Sports', 'Travel'] (23%); ['Tec
    Steps 6-8: ['Fashion', 'Sports', 'Food'] (36%); ['Sports', 'Food', 'Travel'] (14%); ['Fas
```

Interpretation:

The DQN learns a form of *adaptive exploration*: in early steps (when click history is sparse), it tends to show more diverse assortments that help identify the visitor type from their click responses. By the late steps, accumulated click counts shift the state vector toward a recognisable pattern, and the agent concentrates on assortments containing that type's preferred categories — maximising the match score and thus conversion probability.

The static policy always shows (Tech, Fashion, Sports), which happens to include each type's single top category. However, it cannot adapt to also include the second-preference category (Travel for Tech enthusiasts and Fashionistas; Food for Sports fans). The DQN's personalisation advantage is largest for visitor types whose second-preference category falls outside the static assortment.
